LING/COMP 445, LING 645 Problem Set 4

Due before 10:05 AM on Thursday, November 4, 2021

There are several types of questions below.

- For questions involving answers in English or mathematics or a combination of the two, put your answers to the question in an **Answer** section like in the example below. You can find more information about LATEX here https://www.latex-project.org/.
- For programming questions, please put your answers into a file called ps4-lastname-firstname.clj.

 Be careful to follow the instructions exactly and be sure that all of your function definitions use the precise names, number of inputs and input types, and output types as requested in each question.

For the code portion of the assignment, it is crucial to submit a standalone file that runs. Before you submit ps4-lastname-firstname.clj, make sure that your code executes correctly without any errors when run at the command line by typing clojure ps4-lastname-firtname.clj at a terminal prompt. We cannot grade any code that does not run correctly as a standalone file, and if the preceding command produces an error, the code portion of the assignment will receive a 0.

To do the computational problems, we recommend that you install Clojure on your local machine and write and debug the answers to each problem in a local copy of ps4-lastname-firstname.clj. You can find information about installing and using Clojure here https://clojure.org/.

Once you have entered your answers, please compile your copy of this IATEX into a PDF and submit

- (i) the compiled PDF renamed to ps4-lastname-firstname.pdf
- (ii) the raw LATEX file renamed to ps4-lastname-firstname.tex and
- (iii) your ps4-lastname-firstname.clj

to the Problem Set 4 folder under 'Assignments' on MyCourses.

Example Problem: This is an example question using some fake math like this $L = \sum_{0}^{\infty} \mathcal{G}\delta_{x}$.

Example Answer:

Put your answer in the box provided like this.

Example answer is $L = \sum_{0}^{\infty} \mathcal{G} \delta_x$.

Problem 1: In this problem set, we are going to be considering a variant of the hierarchical bag-of-words model that we looked at in class. In class, we used a Dirichlet distribution to define a prior distribution over θ , the parameter vector of the bag of words model. The Dirichlet distribution is a continuous distribution on the simplex—it assigns probability density to all the uncountably many points on the simplex.

For this problem set, we will be looking at a considerably simpler prior distribution over the parameters θ . Our distribution will be *discrete*, and in particular will only assign positive probability to a finite number of values of θ . Further, for the purposes of this problem set where we will only be scoring strings rather than generating them, we will ignore the probability of the 'stop symbol.

The probability distribution is defined in the code below:

```
(def vocabulary '(call me ishmael))
(def theta1 (list (/ 1 2 ) (/ 1 4 ) (/ 1 4 )))
(def theta2 (list (/ 1 4 ) (/ 1 2 ) (/ 1 4 )))
(def thetas (list theta1 theta2))
(def theta-prior (list (/ 1 2) (/ 1 2)))
```

Our vocabulary in this case consists of three words. Each value of θ therefore defines a bag of words distribution over sentences containing these three words. The first value of θ (theta1) assigns $\frac{1}{2}$ probability to the word 'call, $\frac{1}{4}$ to 'me, and $\frac{1}{4}$ to 'ishmael. The second value of θ (theta2) assigns $\frac{1}{2}$ probability to 'me, and $\frac{1}{4}$ to each of the other two words. The two values of θ each have prior probability of $\frac{1}{2}$. Assume throughout the problem set that the vocabulary and possible values of θ are fixed to these values above.

In addition to the code above we will be using some helper functions defined in class:

```
(defn score-categorical [outcome outcomes params]
  (if (empty? params)
    (throw "no matching outcome")
    (if (= outcome (first outcomes))
      (first params)
      (score-categorical outcome (rest outcomes) (rest params)))))
(defn list-foldr [f base lst]
  (if (empty? lst)
   base
    (f (first lst)
       (list-foldr f base (rest lst)))))
(defn log2 [n]
  (/ (Math/log n) (Math/log 2)))
(defn score-BOW-sentence [sen probabilities]
  (list-foldr
   (fn [word rest-score]
     (+ (log2 (score-categorical word vocabulary probabilities))
        rest-score))
  0
  sen))
(defn score-corpus [corpus probabilities]
  (list-foldr
   (fn [sen rst]
     (+ (score-BOW-sentence sen probabilities) rst))
  0
```

Recall that the function score-corpus is used to compute the log probability of a corpus given a particular value of the parameters θ . Also recall (from the Discrete Random Variables module) the purpose of the function logsumexp, which is used to compute the sum of log probabilities; you should return to the lecture notes if you don't remember what this function is doing. (Note that the version of logsumexp here differs slightly from the lecture notes, as it does not use the & notation, so it takes one argument, log-vals, a list of log probabilities.)

Our initial corpus will consist of two sentences:

Write a function theta-corpus-joint, which takes three arguments: theta, corpus, and theta-probs. The argument theta is a value of the model parameters θ , and the argument corpus is a list of sentences. The argument theta-probs is a prior probability distribution over the values of θ . The function should return the \log of the joint probability $\Pr(C = \text{corpus}, \theta = \text{theta})$.

Use the chain-rule identity discussed in class: $\Pr(C, \theta) = \Pr(C|\theta) \Pr(\theta)$. Assume that the prior distribution $\Pr(\theta)$ is defined by the probabilities in theta-probs, which is a list containing the prior probability of each value of θ (that is, a list with two entries, one for the probability of theta1 and one for theta2).

After defining this function, you can call (theta-corpus-joint theta1 my-corpus theta-prior). This will compute log joint probability of the model parameters theta1 and the corpus my-corpus.

Answer 1: Please put your answer in ps4-lastname-firstname.clj.

Problem 2: Write a function compute-marginal, which takes two arguments: corpus and theta-probs. The argument corpus is a list of sentences, and the argument theta-probs is a prior probability distribution on values of θ . The function should return the \log of the marginal likelihood of the corpus, when the prior distribution on θ is given by theta-probs. That is, the function should return $\log[\sum_{\theta \in \Theta} \Pr(\mathbf{C} = \text{corpus}, \Theta = \theta)]$.

Hint: Use the logsumexp function defined above.

After defining compute-marginal, you can call (compute-marginal my-corpus theta-prior). This will compute the marginal likelihood of my-corpus (which was defined above), given the prior distribution theta-prior.

Answer 2: Please put the answer in ps4-lastname-firstname.clj.

Problem 3: Write a function **compute-conditional-prob**, which takes three arguments: **theta**, **corpus**, and **theta-probs**. The arguments have the same interpretation as in Problems 1 and 2. The function should return the **log** of the conditional probability of the parameter value **theta**, given the corpus. Remember that the conditional probability is defined by the equation:

$$\Pr(\Theta = \theta | \mathbf{C} = \mathsf{corpus}) = \frac{\Pr(\mathbf{C} = \mathsf{corpus}, \Theta = \theta)}{\sum_{\theta \in \Theta} \Pr(\mathbf{C} = \mathsf{corpus}, \Theta = \theta)} \tag{1}$$

Note: don't forget that your compute-conditional-prob should return a log probability.

Answer 3: Please put your answer in ps4-lastname-firstname.clj.

Problem 4: Write a function compute-conditional-dist, which takes two arguments: corpus and theta-probs. For every value of θ in thetas (i.e., theta1 and theta2), it should return the log conditional probability of θ given the corpus. That is, it should return a two-element list of log conditional probabilities, one for each of the two values of θ .

Answer 4: Please put your answer in ps4-lastname-firstname.clj.

Problem 5: Call (compute-conditional-dist my-corpus theta-prior). What do you notice about the conditional distribution over values of θ ? You may want to exponentiate the values you get back, so that you can see the regular probabilities, rather than the log probabilities. Explain why the conditional distribution looks the way it does, with reference to the properties of my-corpus. In particular, if one value of θ has higher conditional probability than the other, say why.

Answer 5: Please put your answer in the box below.

(compute-conditional-dist my-corpus theta-prior) returns (-0.5849625007211563 -1.5849625007211563) which is (2/3 1/3) when squared.

 θ_1 has higher probability since both elements of my-corpus contain call which has the highest probability in θ_1 .

In θ_2 , the word with highest probability is **me** but only appears in one of the elements of the corpus. All the other words in both $\theta's$ have the same probability 1/4. All these reasons explain why the conditional distribution looks the way it does.

Problem 6: When you call compute-conditional-dist, you get back a log probability distribution over values of θ (the conditional distribution over θ given an observed corpus). This is a probability distribution just like any other. In particular, it can be used as the prior distribution over values of θ in a hierarchical bag of words model. Given this new hierarchical BOW model, we can do all of the things that we normally do with such a model. In particular, we can compute the marginal likelihood of a corpus under this model. This marginal likelihood is called a *posterior predictive distribution*.

Below we have defined the skeleton of a function compute-posterior-predictive, which you must complete. It takes three arguments: observed-corpus, new-corpus, and theta-probs. The argument observed-corpus is a corpus which we have observed, and are using to compute a conditional distribution over values of θ . Given this conditional distribution over θ , we will then compute the marginal likelihood of the corpus new-corpus. The function compute-posterior-predictive should return the marginal log likelihood of the new corpus given the conditional distribution on θ .

```
(defn compute-posterior-predictive [observed-corpus new-corpus theta-probs]
  (let [conditional-dist ...
        (compute-marginal ...
```

Once you have implemented compute-posterior-predictive, call (compute-posterior-predictive my-corpus my-corpus theta-prior). What does this quantity represent? How does its value compare to the marginal likelihood that you computed in Problem 2? Why is this to be expected?

Answer 6: Please put your code in ps4-lastname-firstname.clj and write the text part of the answer in the box below.

```
In question 2, (compute-marginal my-corpus theta-prior) returns -6.415037499278844.

Here, (compute-posterior-predictive my-corpusmy-corpus theta-prior) returns -6.2630344058337934

Since the new-corpus is the same as the observed-corpus, this result is to be expected.
```

Problem 7: In the previous problems, we have written code that will compute marginal and conditional distributions *exactly*, by enumerating over all possible values of θ . In the next problems, we will develop an alternate approach to computing these distributions. Instead of computing these distributions exactly, we will approximate them using random sampling.

The following functions were defined in class, and will be useful for us going forward:

```
(defn normalize [params]
  (let [sum (apply + params)]
    (map (fn [x] (/ x sum)) params)))
(defn flip [weight]
  (if (< (rand 1) weight)
   true
    false))
(defn sample-categorical [outcomes params]
  (if (flip (first params))
    (first outcomes)
    (sample-categorical (rest outcomes)
                        (normalize (rest params)))))
(defn sample-BOW-sentence [len probabilities]
  (if (= len 0)
    '()
    (cons (sample-categorical vocabulary probabilities)
          (sample-BOW-sentence (- len 1) probabilities))))
```

Recall that the function sample-BOW-sentence samples a sentence from the bag of words model of length len, given the parameter vector probabilities.

Define a function sample-BOW-corpus, which takes three arguments: theta, sent-len, and corpus-len. The argument theta is a value of the model parameters θ . The arguments sent-len and corpus-len are positive integers. The function should return a sample corpus from the bag of words model, given the model parameters theta. Each sentence should be of length sent-len and number of sentences in the corpus should be equal to corpus-len. For example, if sent-len equals 3 and corpus-len equals 2, then this function should return a list of 2 sentences, each consisting of 3 words.

Hint: Use sample-BOW-sentence. You may also want to use the built-in function repeatedly.

Answer 7: Please put your answer in ps4-lastname-firstname.clj.

Problem 8: Below we have defined the skeleton of the function sample-theta-corpus which you must complete. This function takes three arguments: sent-len corpus-len and theta-probs. It returns a list with two elements: a value of θ sampled from the distribution defined by theta-probs; and a corpus sampled

from the bag of words model given the sampled θ . (The number of sentences in the corpus should equal corpus-len, and each sentence should have sent-len words in it.)

We will call the return value of this function a theta-corpus pair.

Answer 8: Please put your answer in ps4-lastname-firstname.clj.

Problem 9: Below we have defined some useful functions for us. The function get-theta takes a thetacorpus pair, and returns the value of theta in it. The function get-corpus takes a theta-corpus pair, and returns its corpus value. The function sample-thetas-corpora samples multiple theta-corpus pairs, and returns a list of them. In particular, the number of samples it returns equals sample-size.

```
(defn get-theta [theta-corpus]
  (first theta-corpus))

(defn get-corpus [theta-corpus]
  (first (rest theta-corpus)))

(defn sample-thetas-corpora [sample-size sent-len corpus-len theta-probs]
  (repeatedly sample-size (fn [] (sample-theta-corpus sent-len corpus-len theta-probs))))
```

We are now going to estimate the marginal likelihood of a corpus by using random sampling. Here is the general approach that we are going to use. We are going to sample some number (for example 1000) of theta-corpus pairs. These are 1000 samples from the joint distribution defined by the hierarchical bag of words model. We are then going to throw away the values of theta that we sampled; this will leave us with 1000 corpora sampled from our model.

We are going to use these 1000 sampled corpora to estimate the probability of a specific target corpus. The process here is simple. We just count the number of times that our target corpus appears in the 1000 sampled corpora. The ratio of the occurrences of the target corpus to the number of total corpora gives us an estimate of the target's probability.

More formally, let us suppose that we are given a target corpus \mathbf{t} . We will define the indicator function $\mathbb{1}_{\mathbf{t}}$ by:

$$\mathbb{1}_{\mathbf{t}}(c) = \begin{cases} 1, & \text{if } t = c \\ 0, & \text{otherwise} \end{cases}$$
(2)

We will sample n corpora c_1, \ldots, c_n from the hierarchical bag of words model. We will estimate the marginal likelihood of the target corpus \mathbf{t} by the following formula:

$$\sum_{\theta \in \Theta} \Pr(\mathbf{C} = \mathbf{t}, \Theta = \theta) \approx \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}_{\mathbf{t}}(c_i)$$
(3)

Define a procedure estimate-corpus-marginal, which takes five arguments: corpus, sample-size, sent-len, corpus-len, and theta-probs. The argument corpus is the target corpus whose marginal likelihood we want to estimate. sample-size is the number of corpora that we are going to sample from the hierarchical model (its value was 1000 in the discussion above). The arguments corpus-len and sent-len characterize the number of sentences in the corpus and the number of words in each sentence, respectively. The argument theta-probs is the prior probability distribution over θ for our hierarchical model.

The procedure should return an estimate of the marginal (not log) likelihood of the target corpus, using the formula defined in Equation 3.

Hint: Use sample-thetas-corpora to get a list of samples of theta-corpus pairs, and then use get-corpus to extract the corpus values from these pairs (and ignore the theta values).

Answer 9: Please put your answer in ps4-lastname-firstname.clj.

Problem 10: Call (estimate-corpus-marginal my-corpus 50 2 2 theta-prior) a number of times. What do you notice? Now call (estimate-corpus-marginal my-corpus 10000 2 2 theta-prior) a number of times. How do these results compare to the previous ones? How do these results compare to the exact marginal likelihood that you computed in Problem 2?

Answer 10: Please put your answer in the box below.

When running (estimate-corpus-marginal my-corpus 50 2 2 theta-prior), the results are between 0.0 and 0.04

When running (estimate-corpus-marginal my-corpus 10000 2 2 theta-prior), the results are between 0.0095 and 0.0137.

We observe that as the sample size increases, the more the results converges towards 0.01171875 which is the value from Problem 2 making the estimation better.

Problem 11: These functions will be useful for us in the next problem.

In Problem 9, we introduced a way of approximating the marginal likelihood of a corpus by using random sampling. We can similarly approximate a conditional probability distribution by using random sampling.

Suppose that we have observed a corpus \mathbf{c} , and we want to compute the conditional probability of a particular θ . We can approximate this conditional probability as follows. We first sample n theta-corpus pairs. We then remove all of the pairs in which the corpus does not match our observed corpus \mathbf{c} . We finally count the number of times that θ occurs in the remaining theta-corpus pairs, and divide by the total number of remaining pairs. This process is an example of rejection sampling.

Define a function rejection-sampler which has the following form:

```
(defn rejection-sampler
  [theta observed-corpus sample-size sent-len corpus-len theta-probs]
  ...
)
```

This function should use the rejection sampling method (as described above) to estimate the conditional probability of theta, given that we have observed the corpus observed-corpus. The function must estimate this conditional probability by taking sample-size samples (you may assume this argument is a positive

integer) from the joint distribution on theta-corpus pairs. The procedure should filter out any theta-corpus pairs in which the corpus does not equal the observed corpus. If there are no remaining pairs after filtering, then the function should return nil. Otherwise, it should then count the number of times that theta occurs in the remaining pairs, and divide by the total number of those pairs.

Hint: Use get-count or get-counts to count the number of occurrences of theta.

Answer 11: Please put your answer to the coding problem in ps4-lastname-firstname.clj.

Problem 12: Call (rejection-sampler theta1 my-corpus 100 2 2 theta-prior) a number of times. What do you notice? Try with larger sample sizes (such as 200, 500, 1000...). How large does sample-size need to be until you get a stable estimate of the conditional probability of theta1? Why does it take so many samples to get a stable estimate?

Answer 12: Please answer the questions in the box below.

As the sample size increases, the estimate gets more stable. sample-size needs to be around 1000 to get a stable estimate of the conditional probability of theta1. By the law of large number, random sampling gets better as the size increase.
